Hydrological Studies in India During Last Decade: A Review

TANVI ARORA and V M TIWARI*

CSIR-National Geophysical Research Institute, Uppal Road, Hyderabad 500 007, India

(Received on 14 June 2018; Accepted on 15 December 2018)

In the recent past, with the availability of enormous datasets and advanced computational skills, hydrological science is trending towards integration of multidimensional studies for the comprehension of complete hydrological cycle. Numerous studies have been carried out in varied hydrological, climatic and geological settings of India during the last decade. These studies cover groundwater exploration and management; surface water-groundwater interactions; geogenic and anthropogenic contaminations; water balances; predictive modelling and others. This article provides a glimpse of these studies. Some reports and studies might not have been described here due to their unavailability in the public domain and due to space limitation.

Keywords: Hydrological; Multidimensional Studies; Computational Skills; Anthropogenic Contaminations

Introduction

India has a great hydrological and climatic diversity; from alluvial plains to hard rock aquifers and Thar Desert, Rajasthan having rainfall less than 250 mm/yr to Mawsynram, Meghalaya recording 11,872 mm/yr. These diversities, along with uneven demand of water, are posing a challenge for management of water resources in India. India is bestowed with a large amount of annual rainfall and total average annual river flow is 1953 km$^3$ while the annual utilisable surface water is estimated to be around 690 km$^3$ (Kumar et al., 2005). The total annual replenishable groundwater resources and the net annual groundwater availability as on March 2011 of the country have been assessed to be 433 km$^3$ and 398 km$^3$ respectively while the annual groundwater draft for all uses is 245 km$^3$ (CGWB, 2014-2015). Aquifers in India are broadly categorised as consolidated and unconsolidated formations (Fig. 1). The water resources of India and other related information are summarized in Table 1. Almost 83% of the water resources are being used in the agriculture sector and the rest are utilized for domestic, industrial and other activities (Table 2). The distribution of groundwater in the country is highly diverse and the availability of safe drinking water from many aquifers is restricted due to geogenic contaminants. Considerable decline of well yields and the depletion of groundwater levels are the major concerns. The situation is further worsened due to the water contamination, and extreme conditions of climate variability including floods and droughts. Extreme climatic events pose more challenges to groundwater management plans. The various geo-spatial datasets related to hydrology (including topography, Land Use Land Cover (LULC), soil etc) are available through open sources like Bhuvan (http://bhuvan.nrsc.gov.in) and India-Water Resources Information System (India-WRIS, http://www.india-wris.nrsc.gov.in/) which are routinely used for governance, administrative purpose as well as research in hydrological sciences.

Surface Water Resources

Surface water hydrology includes water availability analysis, flow duration curve analysis and environmental flow requirement, flood estimation and routing, structural and non-structural measures of flood management, snow and glacier melt monitoring and modeling, sedimentation studies for flood control etc.

*Author for Correspondence: E-mail: virendra.m.tiwari@gmail.com
Almost 61.5% of utilisable water available within the country belongs to the surface water resources.

Glaciers and snow cover play a pivotal role in controlling the headwater river run-off variability of monsoon influenced areas (Thayyen et al., 2007). A positive regional mass balance as well as reduction of river runoff for the period 1999 to 2008 is reported from the Hindu-Kush-Karakoram-Himalaya glaciers and it is suggested that the contribution of Karakoram glaciers to sea-level rise is 0.01 mm/yr (Gardelle et al., 2012). A consistent and prolonged negative mass balance in Western Himalaya from 1997 to 2014 is ascribed to the increased supraglacial debris cover (Pratibha et al., 2018). It is proposed that this approach of finding debris cover can be adopted to study the effect of climate change with respect to mass balance and increase in the number of supraglacial and moraine dammed lakes on much larger spatial scale in different regions of Himalaya. Glacier-mass balance approach was adopted to infer the high-altitude precipitation in the upper Indus Basin and it was shown that the amount of precipitation required to sustain the observed mass balance of large glacier systems is far beyond that at valley stations or estimated by gridded precipitation products (Immerzeel et al., 2015). The findings from this study had an important bearing on climate change impact studies, planning and design of hydropower plants and irrigation reservoirs. Haritashya et al. 2010 made a detailed study of the temporal variations in particle size, texture, mineralogy, origin and evacuation pattern of the sediments based on studies on the proglacial meltwater stream of Gangotri glacier for the period 2000-2006. A study related to climatic processes and their genesis is carried out in middle Satluj Valley, western Himalaya (Sharma et al., 2017). Pottakkal et al. (2014) attempted dye tracer experiments to characterize the subglacial pathways that transport the meltwaters from glaciers through the lower ablation zone of the Gangotri glacier. The studies mentioned that the actual snowmelt contribution remains speculative under both present and future climatic conditions (Siderius et al., 2013).

A regression model for runoff forecasting is developed using available hydro-meteorological data within a glacial valley (Srivastava et al., 2014). Twenty-five flood events are correlated with sediments which were generated and transported from higher Himalayan crystalline and the trans-Himalaya regions. These events were supposed to be generated by landslide lake outburst floods during precipitation. The coupling between the moisture bearing monsoon circulation and southward penetrating mid-latitude westerly troughs were implied for extreme precipitation events and such outburst floods.

Most of the Indian river basins are climate sensitive and the study of their sediments provides a better understanding of continental-scale fluvial system, variations in weathering and erosional processes over the whole subcontinent. The river Ganga, originating from Himalaya, is the most dynamic among world’s major rivers. The sediments of the Ganga river were analyzed for its textural properties (characterized by fine to very fine sand at Himalaya organic belt; medium to fine sand at northern Indian craton and very fine sand to clay at alluvial plain region), grainsize characteristics (nearly 80% of bedload sediment to be transported as graded suspension) and transportation dynamics (extremely
high rate of water discharge, huge sediment load during monsoons and high discharge variability) by Singh et al. (2007).

The effective discharge for suspended sediment transport in the alluvial reaches of Ganga River in the Western Ganga Plains was computed using analytical and an alternative magnitude-frequency approach. It was concluded that the effective discharges at different places have recurrence interval of 1-2 years and are channel maintaining (Roy et al., 2014). It was proposed that the changes in the effective discharge (monsoonal fluctuations) influenced the long-term landscape development and valley filling episodes in the Ganga river plain. Hydrology and sediment dynamics were linked to landscape diversity in the Ganga dispersal system (Roy et al., 2017).

Mahi River basin in western India, was quantified for contemporary and paleo-discharges and the changes in the hydrologic regime through mid-late Holocene. In this river basin the discharge estimates were based on the channel dimensions and established empirical relations for mid-late Holocene,
historic and the present ones. It was inferred that the precipitation is showing a decreasing trend since the mid-late Holocene (Sridhar, 2007). Important hydrological features of the flood region were investigated to treat entire Damodar river system from source to mouth. The climatological data along with stream flow records were analysed. The study revealed the significant changes in the hydrological behavior of the region were characterized by an increase in temperature levels and reduction in rainfall and river flows (Roy and Majumdar, 2007).

A few other characteristics of surface water resources were made available by other workers. The implications of forest use and reforestation on surface and sub-surface hydrology were explained by Bonell et al., 2010. The importance of soil water retention capacity to maintain the base flow levels and the effect of deforestation was conveyed by Qazi et al., 2017. An integrated approach using remote sensing data, borehole data, field data, isotopic and water level data was adopted to identify major paleochannels and studied their hydraulic connectivity with adjacent alluvial plains, rate and source of natural recharge and the groundwater flow direction (Samadder et al., 2011).

**Groundwater Resources and Aquifer Mapping**

The conventional electrical method (Vertical Electrical Soundings) continues to be the most reliable method for correlating the geoelectrical parameters with lithology to delineate groundwater potential zones. Such studies are carried out in the Tamil Nadu (Ballukaray, 2001) and other parts of the country. A number of researchers have successfully carried out groundwater exploration and modeling to assist in sustainable long-term management of groundwater resources (Mondal and Singh, 2004; Saxena et al., 2005; Mondal et al., 2011). Use of Electrical Resistivity Tomography (ERT) resolved various challenging problems faced by the Geoscientists working with geohydrological and geotechnical methods (Andrade, 2011). Among the other geophysical methods, Mise-le-masse technique to locate the extension of fractures in hard rocks (Kumar et al., 2003), use of gravity methods in crystalline aquifers (Murty et al., 2002), seismic methods for delineation of aquifers (Sundararajan et al., 2004) and integrated studies using hydrogeology (Singh et al., 2003, Dutta et al., 2006, Barker et al., 2003, Sharma et al., 2005, Rai B, et al., 2005, Hodlur et al., 2006, Dar et al., 2017) are successfully employed for groundwater studies. Over the decade, a systematic approach towards mapping of aquifer and groundwater management techniques led to initiation and accomplishment of an ambitious programme of pilot aquifer mapping over the six representative terrains of the country (Ahmed, 2014). An area of approximately 3,264 km² covering Deccan Traps of Maharashtra, desert areas of Rajasthan, Gangetic plains of Bihar, coastal region of Tamil Nadu, contaminated aquifer system of Bihar and hard rock aquifers of Karnataka and Rajasthan were explored. The dual-moment Aero-Electromagnetic methods were effective in delineating the 3D aquifer configurations marking a new chapter in the hydrological science in India. The Heliborne Transient Electromagnetic surveys were used to delineate the aquifer geometry and identify the conductivity patterns in a few chosen areas of hard and soft rock aquifers in the pilot aquifer mapping. These results were used to validate and model the hydrogeology of an area in Rajasthan (Chatterjee et al., 2018).

Remote sensing techniques were applied to assess groundwater favorable zones for development and exploration in and around Guntur area in Andhra Pradesh. It was observed that the deeply weathered pediplain (PPD), moderately weathered pediplain (PPM) and shallow weathered pediplain (PPS) are good, moderate to good and poor to moderate groundwater prospect landform whereas residual hill (RH) was considered as a poor groundwater prospective zone (Subbarao et al., 2001). Further satellite imageries were used to explore the groundwater potential zones and identifying sites for rainwater harvesting sites in Aravalli-Pegmatite Precambrian terrain of Delhi (Mukherjee, 2008). Groundwater flows were delineated by observing the impact of water table variations and depth-dependent fracture connectivity (Guiheneuf et al., 2014). A plan of artificial recharge to groundwater in 22 States/UT of India has been efficaciously implemented by the Ministry of Water Resources (Annual Report, CGWB, 2016, www.cgwb.gov.in).

**Prediction and Modelling**

Monsoon rainfall is a major source of water in India. Indian Meteorological Department (IMD) is the nodal
government agency, which issues seasonal prediction (LRF) based on a statistical forecast system with 8 predictors, which have a strong physical linkage with Indian summer monsoon. Statistical models have their own limitations due to their dependence on interrelationship of predictors (Rajeevan et al., 2008) and therefore, ensemble mean forecast (with an assumption of prediction between 7-45 days) is often adopted Forecast model is improved using bias correction for precipitation and air temperature (Shah et al., 2017). Pattanaik and Kumar (2010) showed that even though the major features of monsoon are predicted successfully in all forecasts between March and May, the significant correlation of ISMR with observations are noticed for forecasts initiated in April only. Ramu et al. (2016) attributed the skill of ISMR to the better teleconnections of El Nino related SST and ISMR in these models and in a recent publication, Ramu et al., (2017) came out with a dynamic prediction system for seasonal summer monsoon rainfall over five homogenous regions of India by showing a higher anomaly correlation coefficient (ACC-0.45). A case study on the semi-arid Musi sub-basin (11,000 Km²) of Krishna Basin was performed using three dimensional MODFLOW model (Massuel et al., 2013) and two water allocation scenarios were assessed and compared. Simulations involving all sources and sinks showed that there is 13% less groundwater available for exploitation as compared to the one modelled on the groundwater availability linked to quantfield fluxes. By integrating complex interactions between components of the water budget in space and time, the groundwater model was able to provide a more comprehensive conceptual assessment of the groundwater-resource sustainability. In turn, this has major implications for the existing water allocation modelling framework used to guide decision makers and water-resources managers worldwide.

Ghosh and Majumdar, (2008) presented a methodology of statistical downscaling based on sparse Bayesian learning and Relevance Vector Machine (RVM) and generated a model at river basin scale for monsoon cycle using General Circulation Model (GCM) simulated climatic variables. To address the problem of handling the dynamic, non-linear and noisy data to understand the physical processes in watershed, Nayak and Sudheer, (2008) came up with a Fuzzy model for reservoir inflow forecasting in the Narmada basin. In addition, Singh et al. (2008) proposed a new conceptual sediment graph models based on coupling of popular and extensively used methods like Nash model based instantaneous unit sediment graph (IUSG), soil conservation service curve number (SCS-CN) method, and Power tawwhich vary in their complexities. Correspondingly, Dhar and Mazumdar, (2009) came up with a hydrological model of the Kangsabati river, West Bengal, with reference to climate change scenario. Parameters (evapotranspiration, transmission losses, potential evapotranspiration and lateral flow) were evaluated and predicted for years 2041-2050 towards sustainable development of the river basin which show an increasing trend over the time period. Singh et al. (2010) deliberated on the impacts of climate change on discharge of River Irrawaddy in the Loktak Lake watershed, which included a wetland in Northeast India. This was achieved by running pattern-scaled GCM output through distributed hydrological models (developed using MIKE-SHE) of each sub-catchment.

In addition to conventional statistical methods, the kernel-based machine learning approaches gained popularity including Artificial Neural Networks (ANNs). Gupta et al. (2011) used the Global Circulation Model (HadCM3) projected data to quantify the impact of climate change on runoff of the lower part of Ganga Basin and upper parts of Mahanadi Basin. Their results predicted a decline in the future climatic runoff in most of the river basins of India as compared to normal climatic runoff further indicating that the agriculture in the eastern India may be more affected due to shortage of surface water availability. Similarly, Islam et al. (2012) assessed the impacts of climate change on streamflow of the Brahmani River basin using Precipitation Runoff Modeling System (PRMS) run under the platform of Modular Modeling System (MMS). In contrast to this, Goyal et al. (2012) worked on downscaling of the output of GCM to obtain simultaneous projection of mean monthly maximum and minimum temperatures (T-max and T-min) along with monthly precipitation and pan evaporation to lake-basin scale in climatically sensitive semiarid region of India. They used the nonparametric method of K-Nearest Neighbor (K-NN) approach to select the nearest neighbors for projections. Model predictions associated with different climate change and abstraction scenarios in
the Upper Bhima Basin indicated that the continuation of current rates of abstraction would lead to significant groundwater overdraft, with groundwater levels predicted to fall by -6m in the next 3 decades (Surinaidu et al., 2013); Physically-Based Distributed (PBD) hydrological model, the Distributed Runoff and Erosion Assessment Model (DREAM) predicted sediment flow rates and sediment yields in Pathri Rao watershed in Garhwal Himalayas (Ramsankaran, 2013). The hydrological impacts of climate change in Central Indian River basin were studied by Raje et al. (2014) using Variable Infiltration Capacity (VIC) MHM (macroscale hydrologic model). This study showed an increasing trend for summer monsoon surface runoff, evapotranspiration and soil moisture in most of the central Indian river basins. On the other hand, a decrease in runoff and soil moisture are projected for a number of regions in southern India, with important differences arising from GCM and scenario variability using VIC model over Ashfi catchment (Godavari Basin) to evaluate the impacts of LULC changes and rainfall trends on the hydrological variables (Hengade et al., 2016). The hydrologic impacts of climate change in Tunga-Bhadra river basin, India were assessed using HEC-HMS and SDSM models, by comparing present and future streamflow and evapotranspiration estimates (Meenu et al., 2013); Modelling hydrology, groundwater recharge and non-point nitrate loadings were carried out in the Himalayan Upper Yamuna basin by integrating hydrological SWAT model with the MODular finite difference groundwater FLOW model (MODFLOW) and Modular 3-Dimensional Multi-Species Transport model (MT3DMS) (Narula and Gosain, 2013). It also includes studies on rainfall (Menon et al., 2013; Salvi and Ghosh, 2013 etc.), water availability and streamflow (Gosain et al., 2011; Singh and Kumar, 2015), soil erosion (Mondal et al., 2014), water quality (Rehana and Mujumdar, 2012), irrigation demands (Rehana and Mujumdar, 2013), and groundwater availability and recharge (Panwar and Chakrapani, 2013). Also, the advances in computational techniques for the enhanced hydrological modelling in the Indian context were reviewed and discussed by Mondal et al., 2016.

Numerical Weather Prediction model output was used to verify the spatio-temporal monsoon rainfall variability across the Indian region. It was observed that the prediction of dry spell rainfall was more uncertain than that of the wet spell. The percentage area of India under wet conditions (rainfall amount over each grid is more than its daily mean monsoon rainfall) and rainwater over the wet area is overestimated by about 59% and 32%, respectively, in all models (Ranade et al., 2014).

The reliability of hydrological models for prediction in ungauged basins (PUB) was improved. The potential of multi-basin modelling for comparative hydrology using PUB grouped 6000 sub-basins on the basis of similar flow signatures. This gave more insights into the spatial patterns of flow generating process at larger scale (Pechlivanidis and Arheimer, 2015). This hydrological setup was named as India-HYPE (Hydrological Predictions for the Environment).

Tiwari et al. (2018) examined the mid-21st century climate projections over western Himalaya from Coupled Model Intercomparison Project Phase 5 (CMIP5) global climate models under Representative Concentration Pathways (RCP) scenarios (RCP4.5 and RCP8.5). It was proclaimed that the western Himalaya and Satluj River Basin will be warmer by mid-century. Considering the reported models with different assumptions, Chawla and Mujumdar (2018) provided a generalized framework for hydrologists to examine stationarity assumption of models before considering them for future streamflow projections and thereby isolate the contribution of various sources to the uncertainty.

### Changing Scenarios with Climate Variability

#### Climate Dynamics

Impact of the climate change on the water resources of Indian river system using the HadRM2 daily weather data to determine the spatio-temporal water availability in the river systems was quantified (Gosain et al., 2010). In this study, SWAT was used to prepare the distributed hydrological model. Simulations over 12 river basins were made, using the data for over 40 years (20 years for Present and 20 years for Green House Gas or future climate scenario), which revealed that two out of 12 river basins are predicted to be the worst affected (one with respect to floods and other with respect to the droughts). Similar impact study for Bhavanisagar Reservoir of Tamil Nadu was attempted by Wilk and Hughes, (2002). They simulated the impact of land-use and climate change
on water resource availability for Bhavanisagar Reservoir of Tamil Nadu and concluded that the land-use and climatic changes that are likely to occur (apart from extreme events) will have a negligible impact on the yield of the Bhavanisagar Reservoir.

In regional and global modelling studies for climate change assessments, Sen Roy et al. (2007) supported the use of irrigation and agricultural impacts along with land use change and aerosol feedbacks. In their work, they analysed the monthly climatological surface data sets at the regional level over India and showed that agriculture and irrigation can substantially reduce the air temperature over different regions during the growing season. The macro scale study over the tropical site in Gujarat also indicated that the absorbing aerosols delay the growth and promote the early collapse of atmospheric boundary layer (Pandithurai et al., 2008).

The climate change impact on hydrology and water resources was assessed by Majumdar (2008) along with the variability in sustainable water resources planning and management. Further, the role of clouds in affecting the sub-season/intra-seasonal variability of sea surface temperature (SST) and atmospheric convection in the equatorial and South-Eastern Tropical Indian Ocean (SETIO) during monsoon break transitions were analysed by Samala and Krishnan (2008).

The first basin-wide assessment of the potential impact of climate change on the hydrology and production of the Ganges system was presented by Jeuland et al. (2013) as a part of the world Bank’s Ganges Strategic Basin Assessment Program. Based on the series of modelling efforts (including downscaling of climate projections, water balance calculation, hydrological simulation, economic optimization), the General Circulation Models (GCM) were found to be highly variable. This leads to considerable differences in predictions of means flows in the Ganges and its tributaries.

It was submitted that the unsteady nature of the onset phase of the monsoon and the dependency of its migration on regional hydrological processes makes northwestern India, in particular, susceptible to variability and changes (Bollasina et al., 2013). This study used atmospheric general circulation model in a realistic configuration to conduct “perpetual” experiments aimed at providing new insights into the role of land–atmosphere processes in modulating the annual cycle of precipitation over India.

The variations in rainfall indices found to be driven by large scale climate variability in a study of extreme rainfall indices over 57 urban areas of India during the period (1901-2010) gave a future projection of climate for next 50 years upto 2060 (Ali et al., 2014). It was shown that the urban areas with major increase in rainfall maxima under the projected future climate is far larger than the number of areas that experience significant changes in the climate during the 20th century. These results indicated a strong need for urban storm water infrastructure planning and management arising out of climate dynamics. The decrease in the intensities of Indian Winter Monsoon (IWM) and its response to external forcing over the last 250 years were suggested (Munz et al., 2017) as a part of climate variability.

**Contamination of Hydrological Resources**

The groundwater pollution studies routinely carried out by Central Pollution Control Board (CPCB) reported high level of arsenic, fluoride and other industrial hazardous wastes during the last decade. The national compilation of all the relevant information on major geogenic contaminants in and their remediation for major parameters like arsenic fluoride, salinity, iron and manganese, uranium, radon, strontium, selenium and chromium are compiled and reported with special emphasis on Nitrate (CGWB, Annual report, 2014). Geogenic contamination studies in the principal aquifers of local areas of Yavamal Maharashtra. The defloridation units were installed at the community level and improvement in the health was indicated (Gwala et al., 2014).

Arsenic contamination produced from shallow depths in the parts of Damodar fan-delta and west of Bhagirathi river in West Bengal and Bengal basin were reported by many workers. The deep domestic pumping only slightly perturbs the deep groundwater flow system while the substantial shallow pumping for irrigation forms a hydraulic barrier that protects deeper resources from shallow arsenic sources. Michael et al.,(2008), evaluated the sustainability of deep groundwater as an arsenic-safe resource in the Bengal basin. Coyte et al. (2018) demonstrated the enhancement of Uranium mobilization from geogenic
cause to anthropogenic cause. They further stressed the need to revise the current water quality monitoring program in India, measures of evaluation of human health risks in high uranium prevalent areas, improvement of remediation technologies and proper implementation of preventive management practices to solve the problem.

The understanding of hydrochemical parameters and activity of natural radionuclides (H-3) was used to determine the relative age of groundwater in the river basins of Karnataka (Ravi Kumar et al., 2011). On this basis, the agricultural water management (AWM) strategy was adapted with an aim to increase the agricultural production through the enhancement of available water resources while maintaining ecosystem services (Garg et al., 2013). In addition, improvement in the ability to develop Environmental flows assessment (EFA) through difference case studies from rivers across the country resulted in developing sustainable management of the water system (Jain and Kumar, 2014). The major focus for the development of EFA was to create an open database for hydrological, ecological and socioeconomic data, developing hydrology-ecology relationships, evaluation of ecosystem services, and addressing pollution due to anthropogenic activities. The studies on the chromium dumpsites indicated that the leaching of carcinogenic hexavalent chromium from COPR dumpsites leading to groundwater contamination is a major risk to environment (Matern et al., 2017). Renganayaki et al. (2013) developed a concept of inverting the water quality as an effect of recharge to address the geogenic and anthropogenic contaminations.

Participation in international projects supported integrated treatment process for agro-food industry effluents and the municipal wastewater (Annual Report, NEERI, 2012). The concept of “zero emission” and “zero discharge” was also started providing Environmental Impact Assessment (EIA) certifications to different industries which is a landmark achievement.

Origin and Source of Floods in India (Palaeoflood-Hydrology)

Annual flooding of monsoon-fed rivers are caused due to high spatio-temporal variability of rainfall. Paleoflood hydrology, which studies the recent and historic records of large floods is an upcoming field of hydrology. The potential of palaeoflood hydrological studies in the Indian context was highlighted by summarising the results for eight Indian rivers over the last two decades and it concluded that such studies in different hydro-geomorphic regions of India are vital for flood-risk assessment of gauged as well as ungauged rivers (Kale 2008). The study proposed that the potential for palaeoflood analysis was high in Deccan rivers, dominated by favourable lithologies (granite, gneisses, sandstones and quartzites) along with stable boundary conditions. Contrary to this, the potential for palaeoflood studies was low in alluvial rivers particularly in Ganga-Brahmaputra Plains and Gujarat Plains. The study revealed that the potential for reconstructing past or recent natural dam-failure during floods was high in Himalayan rivers. It was clearly pointed out that the real data on extreme climatic events produced by palaeoflood records may help in modelling and predicting the future climate changes. Baker (2008) included new techniques for accurate geochronology of flood sediments to solve the coupled hydraulic calculations.

The fluctuations of the monsoon over the Indian sub-continent, paleo-hydrological changes of two playas, Phulera and Pokharan, in Thar desert were studied by Roy et al. (2009) using stratigraphical, mineralogical, geochemical and optical dating methods. They concluded that the sediment successions in shallow profiles from these two playas contain three and four stratigraphic units along with characteristic geochemical properties. Sridhar (2009) showed an evidence of correlation between the extreme hydrological events in Mahi, Narmada and Tapi river basins and attributed them to the regional monsoon domain. He stressed that the palaeoflood records are of great significance in revealing the magnitude and frequency of large floods.

Challenges Along the Coast (Coastal Hydrology)

The Indian coast line hosts 77 major cities with different challenges such as lack of drainage system, overdraft of groundwater, sea water ingression and variations in agricultural practices while the deltaic plains have their own challenges.

A number of studies were carried out to address the problems arising out of irregular withdrawal leading to saltwater intrusion. A simulation model
based on groundwater quality in the Godavari delta developed by Ghosh (2002) indicates a considerable increase in seawater intrusion. Upstream development and inter-annual variations in rainfall of Indian river basins is likely to cause both episodic (periodic) and chronic (constant) shortages in water supplies downstream. Rapid development of surface and groundwater throughout the basin in India resulted in historically low inflows to the main canals. The situation in these deltas is much worse as widespread seawater intrusion is transforming the fresh groundwater to brackish/saline water (Saxena et al., 2004) even in the channel islands like Pesarlanka (Mondal et al., 2010).

A flow and transport simulation model, on the basis of finite element method, was established to evaluate the effectiveness of planned strategies for pumping, in order to locally control the intrusion (Datta et al., 2009). Submarine groundwater discharge (SGD) with special reference to its prevalence as a source of freshwater and nutrients to coastal ecosystems is prominent in coastal research. Very recent study carried out by National Centre for Earth Science Studies (NCESS, annual report 2016) on geomorphological mapping and submarine groundwater discharge reported the lithology variations, water table fluctuations and hydrochemical heterogeneity along the coastal aquifers of Kozhikode in a scientific manner. Kanagaraj et al., (2018) investigated the influence of seawater intrusion in the coastal aquifers of Kallakkam, Kancheepuram district of Tamil Nadu by using integrated geophysics, geochemical and stable isotopes techniques and recommended various precautions to be adopted. Central water Commission (CWC) recently examined the salination issues of surface to coast with solution specific study (CWC salinity report 2017).

Use of Isotope for Subsurface Studies (Isotope and Tracer Hydrology)

The source of wetland groundwater, surface water-groundwater interaction and mixing of groundwater at different depths of aquifer was understood (Sikdar and Sahu, 2009) using isotopic signatures associated with hydrogeology of East Calcutta Wetlands, a peri-urban inland wetland ecosystem. They utilized hydrogeology and isotope composition of groundwater to understand the present hydrological processes prevalent in the wetland, source of wetland groundwater, surface water-groundwater interaction and mixing of groundwater of various depth zones in the aquifer. Their study concluded that the shallow groundwater has high tritium content due to local recharge whereas the deep groundwater has low tritium due to recharge at distant area. At some places, high tritium in deep aquifer was attributed to mixing of groundwater from both shallow and deep aquifers. Isotopic signatures and geochemical behaviour of groundwater in an arsenic-enriched part of the Ganga Plain helped in characterizing the recharge processes in both the shallow and deeper aquifers (Saha et al., 2011). In the reservoir triggered seismicity area of Koyna-Warna region, a model was conceptualized based on the hydrochemical and isotopic characteristics of different well waters for aquifer breaching and mixing of deep aquifer water with shallow aquifer water due to earthquakes (Reddy et al., 2011).

The stable isotope delta O-18 was used to identify stream and spring origins of a mountainous catchment in a case study from Liddar watershed, Western Himalaya, India (Jeelani et al., 2010). The spatial and temporal distribution of delta O-18 and delta D measurements in precipitation and stream waters were used to distinguish various sources and components of stream flow and to estimate their residence times in snow dominated mountainous catchments of Kashmir Himalaya (Jeelani et al., 2013). Air-mass trajectory analysis to find out the moisture contribution of rains over the Kolkata city indicated that these moisture traces originate from Arabian Sea and travel over dry continental region over the Bay of Bengal before arriving Kolkata (Dar et al., 2017). The same isotope (delta D and delta O-18) along with strontium was used in Indus River water to understand the regional hydrology, water sources, and catchment processes (evaporation, transpiration, recycling and mixing) by Sharma et al. (2017). Isotopic studies in Indus civilization of northwest Rajasthan provided an evidence for the climate change in this region associated with both expansion and contraction of Indus urbanism along the desert (Dixit et al., 2018).

Department of Science and Technology, GOI and Physical Research Laboratory (PRL) funded a programme on Isotopes led by Deshpande and Gupta (2007) under the title “National Program on Isotope
Fingerprinting of Waters of India (IWIN) – a New Initiative”. The major objectives of the program included generation of isotope data for addressing important hydrological questions related to origin of water sources and the processes of redistribution by evapo-transpiration, stream flow generation, groundwater recharge and discharge – from watershed to continental scale; and providing quantitative estimates of residence time of the water and vapour in each hydrological reservoir and the fluxes across them in a temporally and spatially distributed manner.

Applications of Big Dataset from Satellite Observations

Information from big datasets is well presented by applying remote sensing methods and thematic maps. With the latest data acquisition systems, it is now possible to obtain many conclusive results for recharge structure sites, water balance studies, agro-hydrology balance studies, forecasting or predictive studies, basin assessment studies, etc. National Remote Sensing Corporation (NRSC) has been playing a vital role in mapping the resources through satellite images to be used for agriculture planning, atmosphere and climate, water resources and many more. Their major focus is on irrigation infrastructure monitoring and performance assessment, water bodies monitoring, basin level water resources assessment, flood forecasting and inundation modelling studies, reservoir capacity loss assessment, preparation of nationwide Ground Water Prospect (GWP) maps at 1:50,000 scales etc. Their output is beneficial in providing baseline information studies for decision support for effective planning, monitoring and management of water resources so as to prepare frameworks for water resource models. The delineation of water bodies using SAT-1/SAT-2 A WiFS/LISS-III data is useful for mathematical assessment of the data characteristics along the glaciers as well as moraine-dammed lakes. NRSC works closely with CWC in providing exclusive datasets for proper planning. Their involvement in Accelerated Irrigation Benefit Programme (AIBP) helped CWC in proper management of canals as well as irrigation network.

On the basis of the confluence dynamics of the Ganga-Ramganga Valley, detailed analysis of the channel morphology, hydrology and sediment transport characteristics of the different rivers was studied through mapping of channel configuration using multi-date remote sensing images and topographic sheets for 90 years (1911-2000) by Roy and Sinha (2007). Sinha et al. (2008) integrated the hydrological analysis with GIS based floor risk map in Kosi river basin and reported very high discharge variability and high sediment flux from an uplifting hinterland. Sreedevi et al. (2013) showed the efficacy of SRTM DEM and GIS based approach in evaluating drainage morphometric parameters over the conventional methods. Meraj et al. (2015) used Linear Imaging Self-Scanner satellite data and Advanced Spaceborne Thermal Emission and Reflection Radiometer digital elevation model in a GIS environment for assessing the surface hydrological behavior of Lidder and Rembiara watersheds of the Jhelum basin which helped in formulating better flood mitigation strategies in this data scarce part of the Himalayan region. Garg et al. (2017) investigated the capabilities of variable infiltration capacity hydrological model to hydrologically simulate the Pennar basin under LULC scenarios. Chaudhuri et al., (2017) showed that the remote sensing based estimates of impervious surface area in urban hydrology are very important indicators for the assessment of water resource depletion. They also developed a correlation between land-use change and their potential impact on urban hydrology. Sentinel-1 and Sentinel-2 data were used to estimate the seasonal impact of groundwater use in the granitic watershed in South India (Ferrant et al., 2017). Gupta and Singh (2016) discussed the methodology to retrieve the hydro-meteorological parameters estimated from satellite based instruments (including Altimeters, Radar, Optical and microwave radiometers) and their variability in case of extreme conditions of drought and flood over India.

CWC came out with a study for “Reassessment of water availability of River Basins in India using Space inputs” for assessing the average annual water resources in the country (2017). The study was approved by Ministry of Water Resources, River Development and Ganga Rejuvenation (MoWR, RD & GR), Government of India. NRSC developed a tool that integrates all input images like basin boundary, LULC, soil, rainfall, temperature, command area and reservoir mask and generates the outputs in the form of image layers and test files. Various abstractions were estimated for 20 basins/sub-basins of India for
a 30 year period from 1985-2015. Water resource availability at the basin scale was assessed by model outputs from computed groundwater fluxes using the data from CGWB. This study by CWC laid emphasis on basin scale wealth quantification through transformation from present basin terminal gauge site discharge, aggregation to meteorological data based water budgeting exercise through hydrological modelling approach.

Gravity Recovery and Climate Experiment (GRACE) allow the possibility of measuring the spatio-and-temporal variations in total terrestrial water storage giving precise estimates of water storage over different time scales. The study by Tiwari et al. (2009) stressing the depletion of North Indian aquifers alerted the water managers to take precautionary measures. As per the study, the areas showing decrease in groundwater storage fall in the Ganga River Basin, which is densely populated and also a major contributor of agricultural products. Since then, these aquifers are investigated by various research communities for further estimates (Chen et al., 2014, Long et al., 2016). Very recently, the spatial and seasonal variations of the surface water budget are examined (Singh et al., 2017) by using GRACE measured gravity anomalies on earth to estimate Total Water Storage (TWS) content over the NW region of India.

**Critical Zone Studies**

Various processes in the critical zone affect each other directly or indirectly. Integrating these subsurface process is always a challenge due to temporal and spatial variability. Climate change may increase aquifer uses and rates of depletion, thus increasing complexity and challenges of aquifer management. Key climate impacts on aquifers are changes in recharge and discharge zones and volumes, contamination and saline infiltration. Critical zone comprises of the unsaturated zone, all above the water table to the tip of the trees. Unsaturated zone is the most important zone for deciphering the pathways of rainfall recharge as well as the infiltration of contaminants to the aquifer system. This process pertains directly to the climate system as the moisture to the atmosphere is highly dependent on the complexity of a few meters of the sub-surface and is equally important parameter for the long term sustainable monitoring of the aquifers. Kumar et al. (2009), Anoop et al. (2017) and Pal et al. (2017) used the satellite data to retrieve the soil moisture qualities and their variabilities. CSIR-NGRI designed a different experiment to relate the soil moisture (from neutron probe) and resistivity variations in vadose zone through time lapse geophysical datasets and proved the efficacy of fourth dimension (time) parameter for locating the point of recharge as an input to the model (Arora et al., 2016). Geophysical methods gained importance towards studying the small scale variability of critical zone. However, the relationship between soil moisture and electrical resistivity could not be standardized. Parate et al., (2011) argued that electrical resistivity measurements can be used to measure soil moisture content for red soils only. Recently, the information on root zone properties are sought by inversion of crop models (Sreelash et al., 2017) by characterizing soil water reservoir and impact of land use and environmental changes on hydrology of agricultural catchments.

Among 24 Critical Zone Observatories around the globe, there is only one observatory on the Kabini River Basin, Karnataka, in India. Considering the huge land area of the country and varied geological and climatic conditions, it is proposed to consider creation of more observatories within country.

**Diversified Studies for Management Plans at Watershed and Basin Scale**

**Estimation of Water Availability and Budgeting at Different Scales**

The growing demand for groundwater availability and the rapid depletion of resources have opened up a forum to discuss on the extent and spatial distribution of groundwater depletion and the connectivity of aquifer system and its dynamics in terms of geological time span. The water balance of entire India has been studied on daily, monthly and annual time scales (Aggarwal et al., 2013) and it revealed that the VIC model results take into account a large number of parameters influencing the process. Sinha (2015) strongly proposed to design a strategy to understand the geology and geometry of the aquifer system defined by the buried channels in order to get the precise estimation under stress conditions through a 3-Dimensional representation of the paleochannels. Li, Lu et al. (2017) established an understanding of
the present water budget in Himalayan Basins and proposed a two-way coupled implementation of the Weather Research and Forecasting (WRF) Model. The WRF-Hydro hydrological modeling extension package (WRF/WRF-Hydro) was employed in its offline configuration over a 10 year simulation period for a mountainous river basin in north India to capture precipitation and resulting stream flow hydrograph which shows a good correspondence with observation at monthly timescales. They concluded that WRF-Hydro modelling system has the potential for predicting potential changes in the atmospheric-hydrology cycle of ungauged or poorly gauged basins.

**Rural, Peri-Urban and Urban Management**

A significant change in Land-Use and Land-Cover is observed through high resolution satellite data. Roy et al. (2015) have generated LULC maps at decadal intervals for 1985, 1995 and 2005 following the International Geosphere Biosphere Program (IGBP) to meet the global standards of interpretation. Various organizations like The Energy Research Institute (TERI), IISc Bangalore, SaciWaters, etc have extensively worked at local level along with respective municipal corporations to reduce the usage of freshwater and use of contaminated water after treatment. NGO’s have also worked towards the awareness on lake encroachment in order to save them from urbanization. The International Water Management Institute (IWMI) along with IITM undertook a part of international collaborative project to demonstrate the usage of local waste water treatment plants and change in cropping pattern over almost a decade (Jampani et al., 2015).

The lack of technical capacity for the informal construction of small dams in rural India was highlighted by Oblinger et al. (2010). They quantified the seepage loss and thereby came across a strategy to deal with water scarcity. The impact of urbanization on the hydrology of Ganga Basin was studied with quantified observations (Misra, 2011) which revealed the change on water habitats, exports, high concentration of pollution into the rivers, wetlands and reservoirs, destabilize the ecological processes and influence the ecological stability of ecosystems.

It was observed that use of gauge calibrated satellite observations significantly improve the rainfall estimation over the metro cities, in an area with a few rain gauge observations (Mishra 2013). Looking towards another metro city of Kolkata, the impacts of pumping on water sources was reported for planning the future water supply and understanding the threat of contamination (Sahu et al., 2013).

Spatial and temporal trends of mean and extreme rainfall and temperature values for 33 urban centers of Rajasthan helped local stakeholders and water managers to understand the risks related to climate change (Pingale et al., 2014). The rainfall indices over 57 major urban areas were derived for complete century (1901-2010) and future projections were given for next 5 decades from 2010-2060 (Ali et al., 2014).

An experiment was conducted to develop an eco-hydrological model for agricultural practices in rural catchment area, to assess the scope of data collecting strategy in data-scarce region (Jackisch et al., 2014). As a case study of Bangalore city, 26 CMIP5 (Coupled Model Intercomparison Project Version 5) GCMs (General Circulation Model) along with four Representative Concentration Pathway (RCP) scenarios were considered for studying the effects of climate change and to obtain projected IDF relationships. This study helped in quantifying the uncertainties arising from parameters of the distribution fitted to data and the multiple GCM models using Bayesian approach. Markov Chain Monte Carlo (MCMC) method using Metropolis Hastings algorithm is used to obtain posterior distribution of parameters (Rupa et al., 2015). Recently, the high concentration of Black Carbon reported over the high-altitude Himalayan Kashmir Region has posed serious implications for the regional climate, hydrology and cryosphere (Bhat et al., 2017)

**Socio-Hydrology**

An emerging theme related to the applications and use of hydrological results in the development of the society is Socio-Hydrology. It was also proposed as “Hydropsychology’, where the discussions and transactions between humans and water-related activities should be included in water research (Sivakumar, 2011) and later it was called as “Duty of Water” (Wescoat Jr. et al., 2013). The need got materialized as the scale of interpretation of hydrological conditions, land use and available institutional structures influenced the watershed
development (Syme et al., 2012) involving interactions between communities for result oriented data collection and dissemination of information. Now the theories of effective communication entertain the importance of hydrological information to users from socio-economic perspective. The challenging tasks of development in mountains could also be tackled by the interventions of stakeholders and interplay of local practices. As a result of socio-hydrological system adoption in Ladakh area, the irrigation and development characteristics took a positive turn in Upper Indus Basin (Nuesser et al., 2012).

Srinivasan, (2015) argued that there are some challenges in incorporating the feedbacks from people and proposed an alternative approach to use the counterfactual trajectories, which will allow policy insights to be gleaned without having to predict social futures. Again, Srinivasan et al. (2015) came out with a multiple-hypothesis approach in the data scarce region of shrinking Arkavathy River. According to them, the approach not only makes a meaningful contribution to the policy debates but also helps prioritizing and designing of future socio-hydrologic research in the watershed. Very recently, Pande and Sivapalan (2017) developed the economic model with various statistics from agriculture, values, norms, technology, economics, trade, environment in space and time, to explain the necessity of socio-hydrology for global water sustainability.

Department of Science and Technology, Government of India (www.dst.gov.in) pronounced the Technology Mission: WAR for Water which says “Winning, Augmentation and Renovation” in 2009. The main objectives of the mission was to find out inexpensive methods of converting saline water into fresh water; to find out methods of harnessing and managing the monsoon rain water; to manage the flood waters; to carry out extensive research on rain water harvesting techniques and for the proper treatment of waste water; and adoption of preventive and protective methods to preserve the wetlands and issues related to them. The agencies involved came up with viable solutions like installation of membrane based devices to provide safe drinking water; use of advanced aerobic, anaerobic process, membrane process and membrane bioreactor to recycle the domestic sewage water etc.; establishing desalination systems; and adopting various methods of recharge (pits, check dams, artificial dugwells etc) for utilising rainwater harvesting techniques.

**Trans-Boundary Aquifers (TBA) and global networking**

The study of trans-boundary aquifers on the Kosi River basin (Chen et al., 2013) described the characteristics of water hazards in the basin based on the existing literature and site investigations including hydrology and related aspects. The substantial groundwater depletion over the TBA including Indus River plains (over India and Pakistan) was proposed for the first time as the quantitative assessment of TBAs with an aquifer stress indicator for a period of 1960-2010 (Wada et al., 2013) using groundwater abstraction, groundwater recharge and groundwater contribution to environment flow.

The International Hydrological Programme (IHP) 7 contributed largely to elevate India on global platform through imparting water education for sustainable development, to revise the curriculum development along with Asian countries. IHP 7 collaborated with The Energy and Resource Institute (TERI) to provide wider education for sustainable development support to India and to improve cooperation with non-governmental institutions.

There was a call concerned with water technologies organised by the Directorate-General for Research and Innovation of the European Commission (DG RTD) and the Department of Science and Technology (DST) of India. As an outcome of this call, four EU and four Indian projects were selected for funding namely ECO-INDIA (Energy-Efficient, community based water and wastewater treatment systems for deployment in India), NAWATECH (Natural Water systems and Treatment Technologies), SARASWATI (Supporting consolidation, replication and up-scaling of sustainable waste water treatment and reuse technologies for India) and SWINGS (Safeguarding water resources in India with green and sustainable technologies). This joint collaboration led to the evolving technologies for sustainable water/ wastewater treatment, reuse and recycling with an unprecedented scope for replication and joint business development. Indo-EU project “SaphPani” (www.saphpani.eu) funded by EU for collaborative research including 20 partners from India, Sri Lanka, Europe and Australia. The project aimed towards the
improvement of natural water treatment systems including River Bank Filtration (RBF), Managed Aquifer Recharge (MAR) and wetlands in India. The project worked on the case studies in various parts of India, particularly water stressed urban and peri-urban areas.

The India-France SARAL/AltiKa mission is the first Ka-band altimetric mission dedicated primarily to oceanography. The mission objectives were firstly the observation of the oceanic mesoscales but also global and regional sea level monitoring, including the coastal zone, data assimilation, and operational oceanography. SARAL/AltiKa also proved to be a great opportunity for inland water applications, for observing ice sheet or icebergs, as well as for geodetic investigations. The mission ended its nominal phase after three years in orbit and began a new phase (drifting orbit) in July 2016 (Verron et al., 2018).

Data sharing is an important aspect of hydrological science studies, be it modelling or prediction. The H² Network (http://hplus.ore.fr/en/) of hydrogeological research sites from India and Europe was established with an aim to maintain and coordinate a network of experimental sites to exchange the data towards a better understanding of water cycle and of the aquifer system. It also maintains a research partnership between basic research and professional experience. CSIR-NGRI’s Experimental Hydrogeological Park at Chotuppal, Telangana, is one of the research sites in the network. Apart from these, there are many opportunities from DST, India towards collaboration in water science with different countries on the globe.

This review for the period 2001-2018 is showcasing the enormous efforts by Indian researchers in varied fields of surface water and ground water studies. More emphasis is laid to solve the issues related to the coastal hydrology and handling of big datasets acquired by the satellites. This period also witnesses the growth of upcoming areas like palaeoflood hydrology, socio-hydrology, and global networking. The management plans at the watershed as well as basin scale are incorporated in global projects towards sustainable development.
